Appendix

A A Simple Conceptual Framework

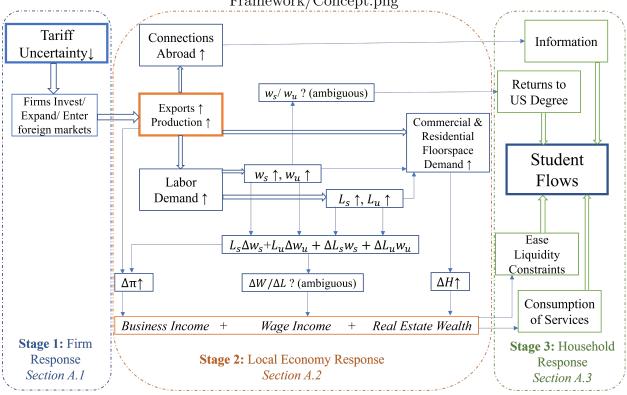

A reduction in uncertainty about the future path of tariffs generates structural change that may affect student flows in different ways. Figure A.1 outlines the primary potential pathways.¹ In the first step, detailed in Section A.1, we describe how changes in tariff uncertainty affect firm investment and expansion in production. As uncertainty declines, firms invest in new capacity and enter new markets that will be lucrative for exporting. If export entry requires a sunk entry cost (Roberts and Tybout, 1997), uncertainty generates an option value for waiting to invest in export-related activities (Handley and Limão, 2017). Feng, Li and Swenson (2017) and Crowley, Meng and Song (2018) also find that a rise in uncertainty reduces foreign market entry. Eliminating the threat of non-NTR tariffs will therefore raise investment, which is seen in the entry of new export firms/varieties, and lowers the prices of Chinese-produced goods, raising the demand for such goods in the US, and other destinations. Access to broad foreign markets spurs domestic Chinese production to outpace domestic demand.

In the next stage of the model, described in Section A.2, we consider how expansions in production affect the local economy. Firm entry and investment lead to an increase in exports, which we consider to be the first step of our empirical analysis (outcomes in orangebordered boxes are shown empirically).

The potential to reach these export markets also encourages firms to invest in expanding manufacturing capabilities, and drives new firm entry and growth. In fact, Appendix B provides empirical evidence for these mechanisms, along with export growth, using pre-WTO data that allows for a two-way fixed effects specification. This may result in higher business income π . Increased firm activity raises labor demand locally, which in turn puts

¹With the dual aim of tractability and allowing for various mechanisms, in the following subsections we model each broad component of the figure rather than a unified general equilibrium model.

Figure A.1: A Simple Conceptual Framework

Framework/Concept.png

Note: The diagram summarizes the outline of the conceptual framework covered in Appendix A; w is wage, and L_s and L_u are employment for skilled s and unskilled u workers; H represents house prices, and π is business profits.

upward pressure on both skilled w_s and unskilled wages w_u . In-migration of skilled L_s and unskilled workers L_u may raise the overall wage bill W, but the change in average wages W/Lis ambiguous as an influx of unskilled workers may lower average wages as the composition of the workforce changes. Yet, overall increases in the wage bill may also increase demand for local business activity, once again increasing business income π .

The increases in wages w_s and w_u have an ambiguous impact on the returns to a college degree and to a US degree. If, for instance, the tariff reductions are more toward low-skill industries, then the increase in w_u may lower college returns. Similarly, if the industries require local knowledge and training, they may lower the returns to a US degree. These factors may lower the flow of students to colleges. If, however, the industries would benefit from more knowledge of the US product market, then the returns to a US degree may increase, and raise the flow of students to universities. As such, the impacts on the returns to a US degree are ambiguous.

The increased firm activity, higher wage and business income, and influx of workers, all raise the demand for commercial and residential floor space. For a less than the perfectly elastic supply of floorspace, this raises the value of both commercial and residential floorspace H. Owners of property see a corresponding increase in real-estate wealth.

The primary goal of our analysis centers around the final stage of our conceptual framework, described in Section A.3. First, we examine how changes to business income, (aggregate) wage income, and real-estate wealth may improve the purchasing power of households in the region. Households that could not afford a US education may now be able to, as this improved purchasing power **eases liquidity constraints**. Furthermore, as households become richer, they may allocate more of their **consumption to services** like US higher education. For both these reasons, improved purchasing power would increase student outflows.

Second, an increase in exports to the US may, of course, lead to improved connections and information about the US. Better **information about collegiate opportunities** abroad may increase student outflows. Finally, the (theoretically ambiguous) changes to the **returns to a US degree** may drive student flows. If the returns increase, it may increase student outflows to the US, and vice versa.

A.1 Firm Response: Exports and Entry Under Uncertainty

The first part of our conceptual framework builds on Handley and Limão (2017), describes how reductions in tariff uncertainty affect firm entry, expansion, and investment, and derives the first part of our empirical analysis: the change in exports with respect to $PNTR_c$.

The base framework is a standard one of differentiated products and monopolistic competition in entry. We suppress the city c subscript for now. Consumers (across the world) have CES preferences over differentiated goods from different firms, and choose how much to purchase each period to maximize consumer utility. Each firm v produces a variety of product i. As a result, demand for product i produced by firm v is q_v , which depends on consumer prices p_v , in the following manner: $q_v = EP^{\sigma-1}p_v^{-\sigma}$, where E denotes total income of the rest of the world, and $\sigma > 1$ is the CES elasticity across products, and $P = \left[\int_v p_v^{1-\sigma}\right]^{\frac{1}{1-\sigma}}$ is the CES price index.²

As in a standard framework, monopolistically competitive sellers draw a productivity $\frac{1}{\omega_v}$, and receive p_v/τ_i , as consumers pay tariff $\tau_i \geq 1$. Firms choose p_v to maximize their operating profit $\pi_v = (p_v/\tau_i - \omega_v)q_v$, and so equilibrium operating profit is given by:³

$$\pi(\tau_i, \omega_v) = \tilde{\sigma} \tau_i^{-\sigma} \omega_v^{1-\sigma} \tag{1}$$

Now we depart from the standard framework to introduce policy uncertainty and sunk entry costs, as in Handley and Limão (2017). Firms pay a sunk entry cost K, and continue to potentially export in the next period with exogenous survival probability $\delta < 1$. In each period, firms observe the firms active in the previous period, and all tariffs and model parameters. If there is no uncertainty in future tariffs, the expected value from exporting after entry e is $\prod_e(\tau_i, \omega_v) = \pi(\tau_i, \omega_v) + \mathbb{E} \sum_t \delta^t \pi(\tau_i, \omega_v)$.

Let $\omega \sim G_i(\omega_v)$. As such, the marginal firm that enters is a firm that draws ω_i^* , where the sunk entry cost equals the present discounted value of profits:

$$K = \frac{\pi(\tau_i, \omega_v^*)}{1 - \delta} \Leftrightarrow \omega_i^* = \left[\frac{\tilde{\sigma}}{\tau_i^{\sigma}(1 - \delta)K}\right]^{\frac{1}{\sigma - 1}} \tag{2}$$

When there is uncertainty in tariffs, firms decide on entry based on a Bellman equation, $\Pi = max \{\Pi_e(\tau_i, \omega_v) - K, \delta \mathbb{E} \Pi_e(\tau'_i, \omega_v)\}.$ The solution to this is an optimal stopping problem that defines an interval of τ_i over which a firm enters. So firms enter when tariffs are low, and the marginal entrant's productivity draw is ω_i^{**} . As Handley and Limão (2017) show in

²Since each firm v produces at most one product i, we suppress i when using v (multiple v produce varieties of i).

³We apply the standard markup over cost $p_v^* = \frac{\sigma}{\sigma-1} \tau_i \omega_v$, and we define $\tilde{\sigma} \equiv \sigma^{-\sigma} \left[(\sigma - 1) P \right]^{\sigma-1} E$.

their Appendix AA, $\omega_i^{**} = \omega_i^* U_i$, where $U_i \leq 1$ is the uncertainty factor and depends on the expected distribution of future τ_i . As they describe, the uncertainty factor is a function of the difference between the tariffs "threatened" if China's MFN status is terminated and the actually applied MFN tariffs. Before 2001, there existed a positive probability that China's MFN status would be eliminated. So, one can derive the uncertainty factor as a function of the "NTR Gap", where the *changes* will be determined by *changes in the probability* that MFN status is terminated (given that the non-NTR tariff rates do not change).

Let us now re-introduce the city c subscript. Export revenue for each firm v is $X_v = p_v q_v = \tilde{\sigma} \sigma \tau_i^{1-\sigma} \omega_v^{1-\sigma}$. If N_{ci} are the mass of potential exporters of product i, then the mass of active firms is $N_{ci} \times G(\omega_i^{**})$. Export revenue for product i is:

$$X_{ci} = N_{ci} \int_0^{\omega_i^{**}} X_v dG(\omega) = \tilde{\sigma} \sigma \tau_i^{1-\sigma} N_{ci} \int_0^{\omega_i^{**}} \omega_v^{1-\sigma} dG(\omega)$$
(3)

To derive a closed-form gravity equation, we rely on Chaney (2008) and assume productivity is from a Pareto distribution $G(\omega) = (\omega/\bar{\omega})^k$, and $k > \sigma - 1$. This allows us to derive: $X_{ic} = \tilde{\sigma} N_{ci} \tau_i^{-k} \tilde{U}_i$, where $\tilde{U}_i \equiv U_i^{(k-(\sigma-1))}$ and $\tilde{\sigma}$ is a function of $\sigma, \delta, k, P, K, E$ and $\bar{\omega}$.

When tariff uncertainty changes, tariffs τ_i may stay the same, even as $\Delta \tilde{U}_i \neq 0$. Again, this reflects the fact that the probability of moving to non-MFN tariffs on China (or the "threat") is severely reduced. The percent change in city-level exports, would be a function of changing $\Delta \tilde{U}_i$:

$$\frac{\Delta X_c}{X_c} = \frac{1}{X_c} \sum_{i} \left(\tilde{\tilde{\sigma}} N_{ic} \tau_i^{-k} \times \Delta \tilde{U}_i \right) = \frac{1}{X_c} \sum_{i} \left(\tilde{\tilde{\sigma}} N_{ic} \tau_i^{-k} \tilde{U}_i \times \frac{\Delta \tilde{U}_i}{\tilde{U}_i} \right) = \sum_{i} \frac{X_{ic}}{X_c} \times \frac{\Delta \tilde{U}_i}{\tilde{U}_i} \quad (4)$$

As Handley and Limão (2017) argue, MFN status reduced all policy uncertainty ($\tilde{U}_{i,MFN} =$ 1 for all *i*), whereas, in the non-MFN world, $1/\tilde{U}_{i,0}$ was directly a function of the ratio of the MFN and non-MFN tariffs. As such, $\frac{\Delta \tilde{U}_i}{\tilde{U}_i} = 1 - \frac{1}{U_{i,0}} = \frac{1}{\beta_x}NTR \ Gap_i$. So the percentage change in the product-specific uncertainty is a function of the NTR Gap of the product: $NTR \ Gap_i \equiv \beta_x \frac{\Delta \tilde{U}_i}{\tilde{U}_i}$. These uncertainty changes directly affect exports, based on the baseline propensity to export. So we define $PNTR_c \equiv \sum_i \frac{X_{ic}}{X_c} \times NTR \ Gap_i$.

Together, this motivates our empirical shift-share specification for exports: $\frac{\Delta X_c}{X_c} = \beta_x PNTR_c$. It is a theoretical foundation for our primary estimation equation, which constructs the city exposure measure. Industry shares of total exports in a city determine its exposure to changes in tariff uncertainty, while the shock is provided by the exogenous change in the uncertainty factor, proxied by $PNTR_c$. Empirically, we provide "Identification Checks" in the main paper that check for pre-trends in exports and related outcomes, and we also provide a separate specification in Appendix B which includes growth in entry and investment rates by PNTR exposure. In the 1997-2006 period, there is a clear relative rise in exports to the US specifically after 2001 in more exposed cities. Similarly, these cities experience relatively higher entry rates in manufacturing along with increased investment rates.

A.2 Local Economy Changes: Profits, Wages, Real Estate Income

Why rely on $PNTR_c$ as the shock to capture China's trading environment, or its gain of market access? Furthermore, why might this be relevant in explaining other broader mechanisms that we examine to explain the rapidly increased demand for U.S. higher education? Erten and Leight (2020) describe a structural shift in China through export-led expansion accelerated after accession to the WTO in 2001. Therefore, this setting provides a unique possibility to study the response to trade liberalization. However, China already faced fairly low applied tariffs, and, for example, guaranteed MFN status from Europe.⁴ For this reason, the reduction in uncertainty from the U.S. has been brought forward as an important reason for China's export boom, which accelerates after 2001 (Handley and Limão, 2017). Given the U.S.'s large share of world expenditure, it is plausible that the threat of losing access to that market was an important hindrance to investment and export entry, and that there is a structural break in these after WTO entry. In this case, it would also be industries most

 $^{^4\}mathrm{We}$ show in our analysis that the main export response after 2001 is to the U.S. and not to Europe nor other non-US destinations.

exposed to the threat of high tariffs that were "held back", as proxied by the NTR gap.

Trade liberalization can also be viewed as access to a larger market size, with accompanying rises in entry and competition (Melitz and Ottaviano, 2008). Our Stage 1 response in Figure A.1 places firm investment and entry into foreign markets as the direct consequence of the drop in uncertainty. Our reduced form specification in the main analysis allows us to pick up the possible effects on the domestic economy as a consequence of the structural changes initiated by a rise in access to foreign markets.

The entry of firms can have substantial impacts on the local economy. As firms enter and produce more, it will increase profits π , employee compensation W, and real estate income H. For instance, from the above framework in Section A.1, we know $\pi_v = \frac{1}{\sigma} X_v$, and so a simple rescaling should generate a similar response to $PNTR_c$.⁵

Similarly, an expansion in production, will increase firm demand for different types of labor (skilled and unskilled), and commercial real estate. For tractability, we had assumed above a single homogeneous input into production, but can consider the cost term ω_v to also depend on various factor inputs. In the spirit of tractability, we refer the reader to the middle portion of Figure A.1 to understand how changes in factor input demand would affect the local economy.

A few factors determine changes in prices. First, the relative productivity of each type of labor would affect the demand for skilled L_{sc}^{D} and unskilled labor L_{uc}^{D} labor from firms. Cities that have firms that produce more skill-biased products are likely to demand more skilled labor *ceteris paribus*. As demand for such labor increases, it would tend to raise the skilled w_{sc} and unskilled real wage w_{uc} . Yet, as workers migrate to the city in response to higher real wages, it would also change the supply of L_{sc}^{S} and L_{uc}^{S} . In a (spatial) labor market equilibrium, the supply and demand for labor in each city, for each type of labor equilibrate.

What happens to average wages in city c? The change in average city real wage is ambiguous as it depends on not just the (labor) demand forces, but also the change in the

⁵That is, $\frac{\Delta \pi_c}{\pi_c} \equiv \sum_i \frac{\Delta \pi_{ic}}{\pi_c} = \sum_i \frac{(1/\sigma)\Delta X_i}{(1/\sigma)X_c} = \sum_i \frac{X_{ic}}{X_c} \times \frac{\Delta \tilde{U}_i}{\tilde{U}_i}.$

composition of the workforce. For instance, even though w_{sc} and w_{uc} increase faster in cities with favorable $PNTR_c$, a relatively large influx of low-wage L_{uc} would lower the average wage. This is easy to see if we define average wages as W_c/L_c , where $W_c = w_{uc}L_{uc} + w_{sc}L_{sc}$ is the total wage bill, and $L_c = L_{uc} + L_{sc}$. So the change in average wages is a function of not just the changes in compensation to each skill-type, but also the changing composition of the workforce.⁶

Similarly ambiguous is what happens to the returns to skill $\frac{w_{sc}}{w_{uc}}$ as both the numerator and denominator may increase in cities that have favorable $PNTR_c$.

Finally, the entry of firms and the in-migration of workers would both increase real estate demand. As entering firms look for commercial real estate, the supply elasticity of commercial floorspace will determine the increase in the value of the commercial real estate. This would increase rents H_c^{com} , and incomes of owners of commercial real estate. Similarly, the in-migration of workers L_{sc} and L_{uc} will increase the demand for residential real estate, and once again, the housing supply will determine how rapidly this influx of workers will raise residential rents H_c^{res} . The increase in overall income accruing to owners of real estate H_c is a weighted average of the increases to H_c^{com} and H_c^{res} .

Overall increases in income (GDP) are the sum of the increases in profits Π_c , total wage bill W_c , and real estate incomes H_c . GDP per capita, however, also depends on the change in the composition of the workforce, as an increase in low-wage migration may theoretically lower average wage income.

A.3 Household Response: Liquidity Constraints, Changes in Returns, Expenditure Shares, and Information

Finally, we outline a simple framework that captures the four primary driving forces of our model: how student outflows depend on changes to the information, returns to a US degree, eased liquidity constraints, and shifting one's expenditure share to more services.

⁶That is, the change in average wage income is $\frac{\Delta w_{uc}L_{uc} + \Delta w_{sc}L_{sc} + w_{uc}\Delta L_{uc} + w_{sc}\Delta L_{sc}}{\Delta L_{uc} + \Delta L_{sc}}$.

We keep the framework tractable to derive simple takeaways.

Households begin with household wealth Y. Changes to household wealth may be a consequence of increased profits π , wage income W/L, and real estate income H. Let the cost of domestic education (at the origin o) be κ_o , and the additional cost of getting a degree from the US be κ_d . These additional costs can include the time and effort taken to find out more information about the degrees abroad, and knowing how to apply. These preparations and applications only raise the probability of getting a US degree, as being admitted is not certain. Families can choose how much to invest in improving the probability of getting a US degree s, at a per unit cost of κ_d . Those with a domestic education earn w_o , and if one gets a degree from abroad, they earn a wage premium γ . As such, the expected value of future earnings would be $w_o + \gamma s$.

Changes in Returns and Information: Even in the absence of borrowing constraints or a consumption utility value of a US degree, an increase in exports may affect student flows by changing the returns to a US degree or increasing the information available to potential applicants. Let the additional cost of a US degree be quadratic: $\kappa_o + \kappa_d s + \frac{1}{2}\kappa_{d2}s^2$. To maximize utility in this case, households would simply maximize their lifetime income by choosing how much to invest in trying to get a US degree:

$$\max_{s} Y + (w_o + \gamma s) - (\kappa_o + \kappa_d s + \frac{1}{2}\kappa_{d2}s^2)$$

The first order condition with respect to s suggests:

$$s^* = \frac{\gamma - \kappa_d}{\kappa_{d2}}$$

This equation shows that an increase in the returns to a US degree γ would increase potential outflows abroad. Yet, if the trade expansions actually lowered these returns, there may be fewer students investing in going abroad. Furthermore, better information about US degrees and universities (as a result of trade connections with the US) may lower the costs of getting a US degree (κ_d and κ_{d2}) and raise the share of students investing in going abroad.

The channel described here plays a unique role in that it is about the pairwise relationship between China and the US, where more connections to the US drive flows to the US. The mechanisms below (such as increased incomes), may drive flows to many other destinations.⁷

Liquidity Constraints: Suppose education is an investment rather than a consumption good. In that case, a response to income shocks may imply that households have borrowing constraints to fund their education (in this case, their education abroad). Indeed, as Bound et al. (2020) discuss, almost all the educational expenditures for international students from China are paid by their families, rather than via scholarships or loans. Let us return to the simple cost of a US degree being: $\kappa_o + \kappa_d s$. The difference in prices κ_d (home versus foreign tuition) determines the magnitude of the educational response to income shocks.

Households choose where to invest in education when young, and how much to borrow from the future \bar{b} . They maximize their two-period utility: $u(c_1) + \beta u(c_2)$, where $\beta \leq 1$ is a discount factor, and c_1 is the numeraire.

Period 1 consumption depends on wealth Y, the price of education at home κ_o , the additional price abroad κ_d , and how much they can borrow b from period 2. Period 2 consumption depends on earnings and paying back the period 1 debt with interest R:

$$c_1 = Y - \kappa_o - \kappa_d s + b$$

$$c_2 = w + \gamma s - Rb , \qquad (5)$$

A fraction of households are credit constrained: $b \leq \overline{b}$, where $0 \leq \overline{b} \leq \infty$. For households

⁷Higher incomes may also increase the likelihood of acquiring information (either by easing cost constraints, or consuming more information services). As such, it is a part of the channels described below.

reaching the binding constraint, $b = \overline{b}$, the first-order condition with respect to s is:

$$\kappa_d \, u'(c_1) = \beta \gamma \, u'(c_2) \tag{6}$$

For reasonable assumptions on u(.), for instance, if $u(c) = \log c$, schooling will respond to income shocks, in the manner $\Delta s = \frac{\beta}{(1+\beta)\kappa_d} \Delta Y$, for credit constrained households. For non-constrained households, the education decision does not depend on Y.⁸

Consumption Value of Education: Finally, education may not necessarily be considered just to be investment, but may also have a consumption value. In this case, households may consume education as in any other service. We treat services as having a Stone-Geary utility function and again have other consumption be the numeraire:

$$\max_{s} U = \log(s + \underline{s}) + \log c$$

where $c = Y - \kappa_o - \kappa_d s$. From the first order conditions, we can derive:

$$s^* = \frac{Y - \kappa_o - \kappa_d \underline{s}}{2\kappa_d}$$

The expenditure share on a US education is $\Omega \equiv \frac{s^* \kappa_d}{Y - \kappa_o}$. (Note: κ_o is paid by all regardless of any choices, so net wealth is $Y - \kappa_o$).

$$\Omega = \frac{Y - \kappa_o - \kappa_d \underline{s}}{2(Y - \kappa_o)} = \frac{1}{2} - \frac{\kappa_d}{2(Y - \kappa_o)} \underline{s}$$

If $\underline{s} = 0$, then the demand for services like the US degree would be homothetic, and

⁸In this setup, the only role that changing returns to education (via changes to γ) plays for borrowingconstrained households is in relaxing borrowing constraints. If borrowing is strictly prohibited, $\bar{b} = 0$, then a change in returns does not affect education for borrowing-constrained households.

the expenditure share, in this case, would be a constant $\frac{1}{2}$. But non-homotheticity here (when $\underline{s} > 0$) ensures that the expenditure share on such services increases with net wealth $\frac{d\Omega}{d(Y-\kappa_o)} > 0$.

Together, these four possible channels affect how trade expansions affect the decision to try and obtain a US degree. The different channels have different empirical implications as well. For instance, for returns to change, the relative wages of skilled and unskilled must change. Furthermore, if there is something specific about trade with the US specifically driving more information about the US, then trade with other countries should not drive flows. In contrast, changes to incomes and wealth may drive flows to all countries (not just the US) – the US is just unique in the size and quality of its higher education sector, so it will attract a broader share of this increase. Lastly, while we mention both income and wealth in various parts of our analysis, as the conceptual framework shows, they may both play similar roles in easing liquidity constraints and shifting demand to higher-end services. As such, there is little distinction in the roles they play in eventually driving student flows.

B Exports and Uncertainty

Our conceptual framework in Appendix A is based on the premise that a reduction in uncertainty about the future path of tariffs generates the entry of new firms and investment growth in anticipation of a larger export market. In the next set of results, we check whether the channels highlighted in theory are present in the data. Since entry and investment data are available starting in 1998, and export data in 1997, for these mechanisms where pre-WTO data exists we run a difference-in-difference two-way fixed effects specification:

$$\ln Y_{ct} = \gamma PNTR_c * Post2001_t + \alpha_t + \alpha_c + \delta Z_{ct} + \epsilon_{ct}, \tag{7}$$

where the outcome is exports, new firm entry, and investment. Given the panel setting with at least 3 years of pre-WTO data, we interact the *PNTR* measure with a dummy equal to one when the year is 2002 or later. We include year and city-fixed effects, as well as time-varying controls.⁹ The coefficient γ represents the relative differences in the outcome after 2001 for cities that vary in exposure. Finally, standard errors are clustered at the city level.

The export specification serves as a robustness exercise for the previous results that showed a larger rise in exports in cities more exposed to PNTR. Importantly, we can also differentiate across export destinations. Given that PNTR proxies only for uncertainty with US tariffs, its elimination should be associated with an immediate increase in exports to the US but *not* other destinations. We produce one outcome of exports to the US specifically, an outcome of total exports to Europe, and finally, all non-US destinations. For each of the three destinations, we examine separately a sample of only 1997-2006 along with the full sample. The former sample is comparable to Handley and Limão (2017) and Pierce and Schott (2016), which examine this period immediately after China joins the WTO.

⁹The controls include the previous time invariant controls (industry contract intensity and export license requirement) interacted with the $Post2001_t$ indicator, along with time varying annual import and input tariffs, and also population.

The first three columns in Table B.1 show that comparing the pre-WTO period to the 2002-2006 period results in larger export growth for more exposed cities *only when the outcome is restricted to US exports*. There is a very small and insignificant relative rise in exports to Europe and even all non-US destinations. For the full sample (until 2013), exports grow to all destinations (though still insignificantly so to Europe), but most strongly to the US. Our interpretation is that as firms invest in a market as large as the US, they eventually expand to other markets as well.

In Table B.2, we include new firm entries and investments as outcomes. In Figure A.1, a reduction in uncertainty has a direct impact on firm entry and investment as market access increases. Although the impetus for entry is the new export opportunity, our reduced form specification in the main analysis allows for broader economic impacts, which is why we examine total entry and investment in the manufacturing sector (instead of conditioning on exporters).

We mostly rely on ASIP data, although we supplement entry results with the Economic Census, which covers all firms engaged in economic activities.¹⁰ The first two columns display the results for firm entry in the manufacturing sector with each database, and it is clear that after 2001, PNTR exposure is associated with relatively larger entry rates.

The last three columns display results for separate types of investment rates. First, we add investment of fixed capital to annual *changes in value* of firm equity for "total" investment (which is normalized by total sales).¹¹ Then, we separate these into only "fixed" capital and capital "appreciation". In all cases, there is a relatively higher growth rate of investment rates after 2001 in higher PNTR cities.

 $^{^{10}}$ The ASIP is more comprehensive in terms of firm information, but less representative as it is a survey of firms with more than five million RMB in sales. They are both at the firm level, so we sum all observations in manufacturing to produce city-year observations. See Appendix G for full information on the data used in this subsection and details on the construction of entry and investment rates.

¹¹We do not have capital stocks, so we divide investment by total sales. Firm equity is a stock, so we take the first differences to produce the appreciation of the equity value each year. Both values are constructed with the sum of all firms within a city present in ASIP.

Notes: Tables display results using a diff-in-diff specification similar to that in Pierce and Schott (2016). The coefficient of interest is the interaction of city-level PNTR exposure with a dummy for years after 2001. All columns include city and year-fixed effects. For exports as the outcome in Table B.1, we measure log exports for different destinations: USA, Europe, and all non-USA nations. We also separately show results up until 2006 (cols 1-3), and then also for the full sample through 2013 (cols 4-6). In Table B.2 the number of newly created firms is normalized by the "stock" of firms. To get the stock, we first aggregate all newly created firms from 1990-1996. Then starting in 1997, we construct entry rates as: $Entryrate_{ct} = \frac{newfirms_{ct}}{0.5*Stock_{ct-1}+0.5*Stock_{ct}}$. Although ASIP data starts in 1998, we reconstruct the 1990-1996 period using the birth years reported in the set of firms in ASIP. For investment, we normalize all values by total sales. Notice that since the equity value of a firm is given in stocks, we take the first difference to create "Capital Appreciation". "Total investment" is the sum of changes in equity value and fixed asset investment. Due to the first difference, the data starts in 1999 and we keep the same sample for all three columns. In all specifications, we include controls, with a modification since controls used in our baseline specification (Z_{ct}) are time-variant. First, we include import and input tariffs at the annual level, instead of levels before 2002. Second, the contract intensity and export license controls, which are time-invariant, are interacted with the post-2001 dummy. Finally, we add a time-varying population. Standard errors (in parenthesis) are clustered at the city level. ***p < 0.01, **p < 0.05, *p < 0.1.

C Shift-share Robustness Checks

C.1 Shift-Share Control Variables

The industry balance tests (see Table 1b) identified that two of four known determinants of trade, particularly in the Chinese context, are correlated with industry-level NTR gaps. Specifically, these include industry import tariffs, measured in 2000, and the share of Chinese export revenue covered under direct export licenses, also measured in 2000. Since our primary estimating equation 1 leverages variation across cities, we construct shift-share control variables to account for the potential influence of these industry-level factors. To be conservative, we construct controls for all four of the determinants of trade, even the ones that did not present any pre-WTO correlation with NTR gaps in the industry balance tests – these include industry input tariffs and the measure of industry contract intensity (i.e., the proportion of intermediate inputs employed by firms that require relationship-specific investments by the supplier).

To construct city-level shift share controls, we use a very similar method as in the construction of our PNTR exposure measure, as in equation (3).

$$Z_{c} = \sum_{i} \left(\beta_{ci} \times TFi \right), \quad \beta_{ci} = \frac{X_{ci}^{1997}}{\sum_{j} X_{cj}^{1997}} , \qquad (8)$$

Equation (8) interacts city-industry export shares in 1997 (β_{ci}) with each of the 4 industry-level trade factors (TF_i). These are: (1) Import tariffs, (2) Export licenses, (3) Input tariffs, and (4) Contract intensity. For import tariffs, we use import tariffs measured in 2000 from the World Integrated Trade Solution–Trade Analysis and Information System. We average import tariffs across origins within an industry, to obtain a single import tariff measure for each industry. For export licenses, we use data provided by Bai, Krishna and Ma (2017) on the fraction of total export revenues for a given Chinese industry that is covered under direct export licenses, which is also measured in 2000.

Input tariffs are calculated under standard procedures using import tariffs and the 2002 input-output table for China from the National Bureau of Statistics. The input-output table is comprised of 70 manufacturing sectors called "scodes" which we concord with HS-level import tariffs to produce input tariffs at this level. The input tariffs are a weighted average (given input usage) of the WITS import tariffs on the industries used as inputs. We then re-classify input tariffs using ISIC concordance. While pre-WTO data would be preferred, they are unavailable, and so we use the earliest available year which is 2002.

Lastly, for contract intensity we use data from Nunn (2007), which measures for each industry the proportion of intermediate inputs employed by firms that require relationship-specific investments by the supplier.

As a final note, none of these measures are confounded by the issue of the missing shares described in Borusyak, Hull and Jaravel (2020). When calculating each control, we ensure the set of city-export shares used sums to 1. Because data on contract intensity cover the same 119 industries as our primary PNTR exposure measure, we use the same city-export shares, which sum to 1. The import tariffs, input tariffs, and export license controls have data available for a larger number of industries (145), and so we calculate city-export shares using this larger set of industries, thereby ensuring they sum to 1.

C.2 Shift-Share Balance Checks

Here we describe how primary estimating equation 1 can be transformed to an equivalent industry-level regression equation, as in Borusyak, Hull and Jaravel (2020), to perform the industry balance checks in Table 1b and the regional balance checks in Table 2. In the first step, the primary explanatory variable (i.e., city-level PNTR exposure $PNTR_c$) and any citylevel outcome variables (for regional balance checks) (generically, Y_c) are each individually regressed on the vector of controls (Z_c), and residuals Y_c^{\perp} and $PNTR_c^{\perp}$ are obtained. In the second step, these residuals are then aggregated to the industry level under the form: $\overline{V}_i^{\perp} =$ $\frac{\sum_{c} w_{c} \cdot \beta_{ci} \cdot V_{c}^{\perp}}{\sum_{c} w_{c} \cdot \beta_{ci}}$. Finally, an equivalent industry-level regression specification can be obtained by the general regression equation,

$$\overline{Y}_i^{\perp} = \alpha + \delta \overline{PNTR}_i^{\perp} + \overline{\epsilon}_i^{\perp}, \qquad (9)$$

in which $\overline{PNTR}_i^{\perp}$ is instrumented with the industry shifters $NTRGap_i$, and exposure weights β_i are used as regression weights.

We note that because the industry balance checks require using industry variables, the dependent variable is simply Y_i – i.e., the industry level measure, rather than \overline{Y}_i^{\perp} , the aggregated residuals from the city-level variable Y_c . For the regional balance checks, the dependent variables are the aggregated residuals of the city-level Y_c . Furthermore, the regional balance checks using this industry-level regression yield identical coefficients to replacing the dependent variable in specification 1 with the city-level pre-period variables that we examine.

C.3 Employment Weights

This section explores an alternative strategy that shows that results are similar when using the PNTR exposure measure created with 1990 employment shares instead of exports. This strategy is still closely tied to equation 3, with the difference that we utilize *employment* shares for a given city-industry (*ci*) pair to construct β_{ci} . The NTR gaps are identical. Shares are calculated as $\beta_{ci} = \frac{E_{ci}}{\sum_j E_{cj}}$. The numerator is the total industry employment in 1990 corresponding to city-industry pair *ci*. The denominator is the sum total of 1990 employment across all industries within each city. To avoid the "missing shares" issue described in Borusyak, Hull and Jaravel (2020), the sum of these β_{ci} shares across all industries within the city equals 1, as we only use industries where NTR gaps are available.

Table C.1 replicates the specifications in Table 3 but with the employment shares. Results yield the same qualitative findings, with more precision (higher t-stats) and somewhat larger magnitudes (inter-quartile effects) with employment weights.

| | | | 2002-2013 | | |
|-------------------------------|-------------------------------|---|---------------------------------------|---|---|
| | (1) No Controls | (2) +Control for Contract Intensity | (3) +Control for Import Tariffs | (4) +Control for Input Tariffs | (5) +Control for Export Licenses |

| R2 | 0.064 | 0.085 | 0.093 | 0.103 | 0.115 |

Table C.1: Main Effect on Enrollment with Employment Weights

Notes: City-level regressions show the effect of PNTR exposure on Chinese student enrollment growth between 2002 and 2013, per thousand city residents. PNTR exposure is constructed with 1990 employment shares by industry. Rows below the coefficients scale up the effect size in terms of students per million residents, for a change in the PNTR that traverses its interquartile range (≈ 6 p.p.). In each column, we iteratively include controls. All controls are at the city level, constructed by taking weighted averages of ISIC industries in the same way as the PNTR measure. Notice that the controls are not the same as in the main specification, as now we use employment shares to construct them as well. Contract intensity refers to the Nunn (2007) measure of the proportion of intermediate inputs employed by a firm that require relationship-specific investments. Output tariffs are for the year 2000 (from World Integrated Trade Solution (WITS)), while input tariffs are constructed using WITS tariff data and the 2002 input-output table for China. Export licenses refer to the Bai, Krishna and Ma (2017) measure of the fraction of export revenues licensed to export directly. We report heteroskedasticity-consistent standard errors (in parentheses) at the city level. ***p < 0.01, **p < 0.05, *p < 0.1.

C.4 Rotemberg Weights

We follow Goldsmith-Pinkham, Sorkin and Swift (2020) and construct Rotemberg weights to get a sense of which industries drive the variation in Normal Trade Relations gaps across cities. Table C.2 details the top 30 industries along with the International Standard Industrial Classification industry name. Not surprisingly, the top industries are textiles and apparel. However, outside the top three, there are also chemicals, food, and other miscellaneous industries.

We also conducted a robustness check of our main results by removing the top 5 industries from the construction of our PNTR exposure measure. We thus create a new PNTR exposure measure that is calculated without the top 5 industries. In particular, we drop the top 5 industries from the sample and then construct city-export shares in 1997 (β_{ci}) – in this case, export shares still sum to 1 and are not subject to the issue of the missing shares. We then interact the shares with NTR gaps, as in equation 3, excluding NTR gaps of the top 5 industries. Summing over all industries within the city yields the new PNTR exposure measure that excludes the top 5 Rotemberg weight industries. We then use this as the key dependent variable in regression equation 1. Results yield a coefficient estimate of 0.513 and a standard error of 0.167.

| ISIC | Industry description | Rotemberg weight |
|------|---|------------------|
| 1810 | Manufacture of wearing apparel, except fur apparel | 0.53 |
| 1711 | Preparation and spinning of textile fibers; weaving of textiles | 0.25 |
| 1721 | Manufacture of made-up textile articles, except apparel | 0.16 |
| 2423 | Manufacture of pharmaceuticals, medicinal chemicals and botanical products | 0.15 |
| 1551 | Distilling, rectifying and blending of spirits: ethyl alcohol production from ferment | 0.14 |
| 2691 | Manufacture of non-structural non-refractory ceramic ware | 0.08 |
| 3699 | Other manufacturing n.e.c. | 0.07 |
| 1920 | Manufacture of footwear | 0.07 |
| 3694 | Manufacture of games and toys | 0.05 |
| 2429 | Manufacture of other chemical products n.e.c. | 0.05 |
| 1730 | Manufacture of knitted and crocheted fabrics and articles | 0.05 |
| 2029 | Manufacture of other products of wood; manufacture of articles of cork, straw and pla | 0.05 |
| 2520 | Manufacture of plastic products | 0.04 |
| 1513 | Processing and preserving of fruit and vegetables | 0.04 |
| 1912 | Manufacture of luggage, handbags and the like, saddlery and harness | 0.03 |
| 3210 | Manufacture of electronic valves and tubes and other electronic components | 0.03 |
| 3140 | Manufacture of accumulators, primary cells and primary batteries | 0.03 |
| 2421 | Manufacture of pesticides and other agro-chemical products | 0.03 |
| 3230 | Manufacture of television and radio receivers, sound or video recording or reproduci | 0.03 |
| 2899 | Manufacture of other fabricated metal products n.e.c. | 0.02 |
| 2893 | Manufacture of cutlery, hand tools and general hardware | 0.02 |
| 2022 | Manufacture of builders' carpentry and joinery | 0.02 |
| 3591 | Manufacture of motorcycles | 0.02 |
| 2610 | Manufacture of glass and glass products | 0.02 |
| 1542 | Manufacture of sugar | 0.02 |
| 2925 | Manufacture of machinery for food, beverage and tobacco processing | 0.02 |
| 3150 | Manufacture of electric lamps and lighting equipment | 0.02 |
| 3110 | Manufacture of electric motors, generators and transformers | 0.02 |
| 3693 | Manufacture of sports goods | 0.02 |

Table C.2: Rotemberg Weights by Industry, Top 30

Notes: The table reports the top 30 industries ranked in terms of Rotemberg weights. Rotemberg weights are calculated using the procedure from Goldsmith-Pinkham, Sorkin and Swift (2020). See Goldsmith-Pinkham, Sorkin and Swift (2020) for further details.

C.5 Inference Corrections

We now assess the robustness of our results to various inference corrections. We apply recent insights from Borusyak, Hull and Jaravel (2020) and Adao, Kolesar and Morales (2019) to correct for correlations between the shift-share and residuals across cities with similar exposure shares. Additionally, we apply standard corrections for clustering in spatial designs. Finally, we show results are robust to clustering at the more aggregate province level.

An additional contribution of BHJ is that their transformation of shift-share regression designs from city-to-industrial level variation also includes a new computation of "exposurerobust" standard errors, which account for potential cross-region correlation in residuals. To estimate "exposure-robust" standard errors, we implement our main analysis using the industry aggregation recommended in BHJ, as described in equation (9). Column (1) of Table C.3 shows that the coefficient estimate using the industry-level regression is identical, with standard errors slightly larger than the city-level regression in column (5) of Table 3. Following the suggestion in BHJ, to properly estimate exposure-robust SEs in the next column, we also include in the industry-level regression the two trade-factors that failed industry balance tests in Table 1b as further controls – recall these were the industry-level measures for import tariffs and export licenses. Note that these industry-level controls are included, even after the shift-share controls (Z_c) are partialled-out during the aggregation of variables from city-level to industry level. Hence point estimates in column (2) of Table C.3 differ slightly from the main estimate in column (5) of Table 3. Nonetheless, our results remain significant at the 5% level.

Borusyak, Hull and Jaravel (2020) also recommend examining the mutual correlation of shocks within sectors. To assess this, we use the industry-level regression equation in column (1) and cluster at more aggregate industry levels. Recall our data and design rely on NTR gaps (shifters) at the 4-digit ISIC level. In columns (3) and (4) of Table C.3, we cluster standard errors at the 3-digit ISIC level and also the 2-digit level. Because of the small numbers of clusters at the 2-digit level, we also estimate wild-bootstrap p-values and confidence intervals (Cameron, Gelbach and Miller, 2008), reported at the bottom of the table. Results still remain statistically significant.

Finally, we provide some robustness checks with respect to the spatial clustering of residuals across cities. Here we return to our primary city-level estimating equation (1). In columns (5)-(7) we estimate Conley Spatial standard errors (Conley, 1999). We assess Conley Spatial standard errors by using various distance cutoffs: 50 KMs, 100 KMs, and 200 KMs in columns (5), (6), and (7), respectively. 50km is the average distance to the nearest city in our sample and 200km is the median distance to all cities within a province in our sample. Beyond the cutoff, the correlation between the error terms of two cities is assumed to be zero. Finally, in column (8), we cluster at the province level. Our results remain robust to these checks on spatial clustering.

Table C.3: Robustness: Statistical Inference Based on Alternative Specification and Standard Errors

| | (1) BHJ Shock-Level Regression | (2) BHJ Exposure- Robust SEs | (3) BHJ Cluster on 3-digit ISIC | (4) BHJ Cluster on 2-digit ISIC | (5) Conley Spatial SEs (50 KM Distance) | (6) Conley Spatial SEs (100KM Distance) | (7)Conley Spatial SEs(200KM Distance) | (8) Cluster on Province |
|--------------------|---|------------------------------------|--|--|---|---|---|-------------------------------|
| PNTR Exposure | 0.337^{*} (0.170) | 0.303^{**} (0.151) | 0.337^{**} (0.160) | 0.337^{*} (0.179) | 0.337^{***} (0.119) | 0.337^{**} (0.140) | 0.337^{**} (0.169) | 0.337^{**} (0.162) |
| Number of Clusters | | | 57 | 22 | | | | 30 |

Notes: Table reports results from inference corrections. The coefficient of column (1) is obtained from the industry-level regressions following BHJ, where we use heteroskedasticity robust standard errors (see regression specification details in Appendix C.2). The previous column has the same coefficient as the main specification, however the correct specification should include the industry-level controls that fail balance tests, which we do in Column (2). We cluster the standard errors at the 3-digit and 2-digit ISIC levels in columns (3) and (4) receptively. In columns (5)-(8), coefficients are obtained from the primary city-level estimating equation (1). We assess Conley Spatial standard errors (Conley, 1999) by using various distance cutoffs: 50 KMs, 100 KMs, and 200 KMs in columns (5), (6), and (7), respectively. In column (8), we cluster at the province level. Standard errors are in parenthesis. ***p < 0.01, **p < 0.05, *p < 0.1.

D Heterogeneity in Effects of PNTR

Table D.1 examines whether PNTR exposure affected the composition of students. To help inform mechanisms that we examine in Section 6, we study how effects differed by the level and field of study, sources and amounts of funding, and quality of US institutions attended. Panel A was discussed in the main text, and here we discuss the rest of the results.

Panel B of Table D.1 examines compositional changes by field of study, separately assessing STEM, arts and humanities, and social sciences in columns (2), (3), and (4), respectively. As they comprise a large fraction of international students, business majors are separately shown in column (5). While all fields saw growth in Chinese students, PNTR exposure shifted the composition away from STEM and towards arts and social sciences. Compared to the baseline proportions, our estimates indicate that PNTR exposure increased the share of students in arts and social sciences by 21 p.ps and 13 p.ps, respectively. Business majors, the most popular social science major among international students, also sustained sizable increases in Chinese students. These patterns again may reflect underlying income/wealth accumulation, as STEM degrees are more likely to receive outside funding than non-STEM fields (e.g., business students rely on their own funds).

In panel C, we examine changes in the composition of students by the quality of the US university they attend, grouped into quartiles based on admissions rates – the 1st quartile represents the most selective schools, and the 4th quartile comprises the least selective.¹² There was an increase in enrollment across the quality distribution. The share of Chinese students grew slightly in the 4th quartile and shrank slightly in the 3rd quartile.

In Table D.1 panels D and E, we assess whether PNTR exposure affected the composition of students in terms of the type and amount of funds to finance higher education in the US. Panel D examines the number of students who were funded by scholarships, grants, or other institutional resources ("Has funding") and the number of students who primarily used personal and family income to finance their studies ("No funding"). In 2002, 56% of Chinese

¹²Data on admissions rates come from the Integrated Postsecondary Educational Data System (IPEDS).

students received some form of scholarship, grant, or other financial assistance. Estimates indicate that PNTR exposure induced a large shift in student composition toward unfunded students. Panel E assesses growth in the number of students by quartile of their reported personal funds in 2002. Results indicate compositional shifts among those with substantial personal funds in the 3rd and 4th quartiles. Taken together, this evidence is again consistent with the hypothesis that rising income/wealth helped more students go abroad.¹³

¹³We also investigate whether PNTR exposure induced Chinese students to move to high or low human capital localities in the US. This speaks to whether the rise in educational exports exacerbated or dampened the rise in regional inequality in response to trade-induced labor reallocation. PNTR exposure induced a rise in US services exports for all levels of US commuting zones sorted by baseline human capital. This suggests that the reallocation to educational services dampened the growing disparities across regions induced by labor reallocation to other types of services. Results are available upon request.

Table D.1: Heterogeneity in Effects of PNTR and Composition Changes, 2002-2013

Notes: Regressions show the effect of weighted NTR gaps on Chinese student enrollment growth between 2002 and 2013 per thousand city residents in 2002. We include all main controls. Column (1) reproduces our main estimates from column (5) in Table 3. The first row below the coefficients documents the effect as a fraction of the total effect in column (1). The second row shows the fraction of students of each type in 2002. The final row takes the difference between these two rows and illustrates how the proportional inflow of students attributable to PNTR exposure has changed since the initial proportions in 2002. In Panel B, STEM degrees include degrees in science, technology, engineering, and mathematics. Social sciences also include business-related degrees, and we separately report effects for business only. Panel C uses IPEDS data to create four quartiles of university selectivity based on admissions rates. In Panel D, 'Has funding' refers to students who finance their education only using personal funds. In Panel E, we divide the students by quartiles of personal funds reported used to fund education, where the fourth quartile includes individuals with the most personal funds, and the first quartile are individuals with the least. Heteroskedasticity-robust standard errors reported (in parenthese). ***p < 0.01, **p < 0.05, *p < 0.1.

Table E.1: Summary Statistics

Notes: Data comes from SEVIS individual-level data on student flows, majors of study, and destination universities. 'Students entering US higher education' are measured as a fraction of one million residents in the city. STEM degrees include degrees in Science, Technology, Engineering, and Mathematics. Social sciences degrees also include business-related degrees. University selectivity shares based on admissions rates are from IPEDS data. Universities are categorized into four tiers based on quartiles of the admissions rate. Population and GDP statistics are from the China City Statistics Yearbook.

Notes: The figure shows the NTR gaps for each industry. Green bars plot the difference in NTR and non-NTR tariffs shown in Figure 1c. Data on NTR and non-NTR tariff rates by industry are from Pierce and Schott (2016).

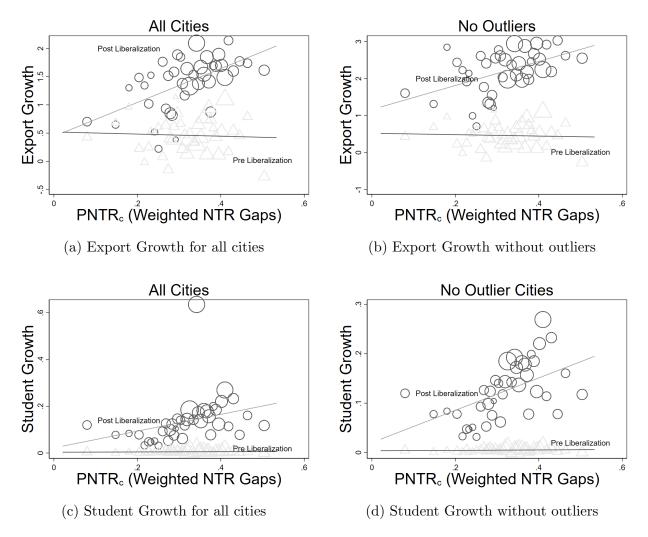

Figure E.2: Correlation between PNTR and Exports and Student Outflows Pre and Post WTO

Notes: The figures show binned scatter plots of the relationship between the weighted NTR gap (PNTR) and growth in outcomes. Unlike Figure 2b, we show the long-differenced growth (for instance, the total change in students between 2002 and 2013). The plots show 40 equal-size bins, weighted by population size in each bin. The right panels drop two cities with the largest student growth (Beijing and Shenzhen) to check for sensitivity to outliers. Post-liberalization export growth is measured as the log change from 2000 to 2013, using data from the China Customs Database, whereas pre-liberalization export growth is measured as the change from 1997-2000. Post-liberalization student growth is measured as the change in students from 2002 to 2013, divided by the initial city population (only non-agricultural hukou) in 2002. Pre-liberalization growth is from 2000-2001. Data on Chinese students by the city of origin are from SEVIS.

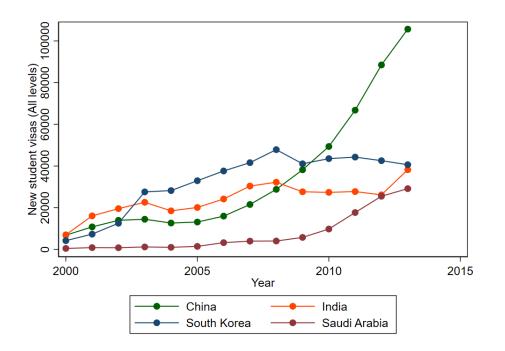

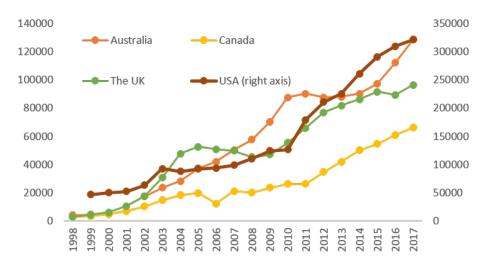

Figure E.3: The Number of New US Student Visas Granted by Country-of-Origin

Notes: The figure shows the number of new US student visas granted to each country of origin. These combine students of all levels (graduate, undergraduate and associate).

Figure E.4: Growth in the Number of International Students from China in Top Four Destination Countries

Notes: The figure shows the growth in the number of Chinese students at the top destinations, as measured in 2017, using UNESCO data. The United Kingdom includes Great Britain and Northern Ireland. Students at all levels and degree types are aggregated here. US enrollment is on the right axis.

Table E.2: The Short-, Medium-, and Long-Run Impacts of PNTR on Student Outflows

Notes: City-level regressions show the effect of weighted NTR gaps on Chinese student enrollment growth, per thousand city residents, over different periods. We examine a shorter-run time frame in column (1), 2002-07. Column (2) examines a medium-run time frame covering the Great Recession and recovery, 2008-10. Column (3) examines student growth over the longer-run period, 2011-13. We include all the main controls. We report heteroskedasticity-consistent standard errors (in parentheses) at the city level. ***p < 0.01, **p < 0.05, *p < 0.1.

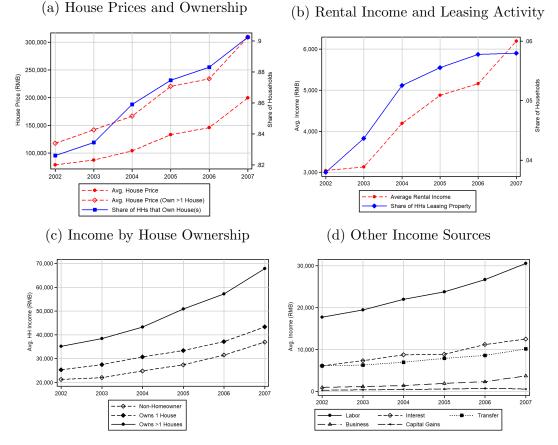

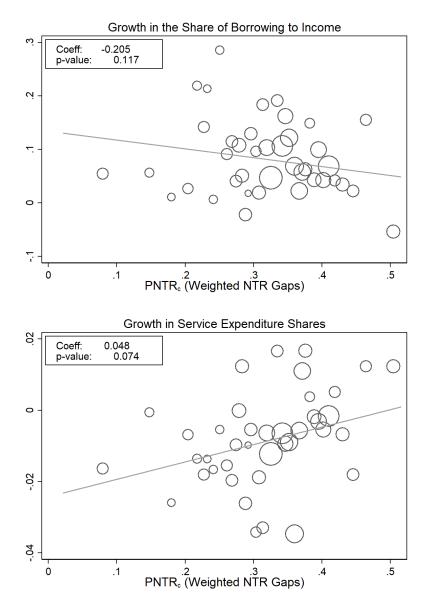

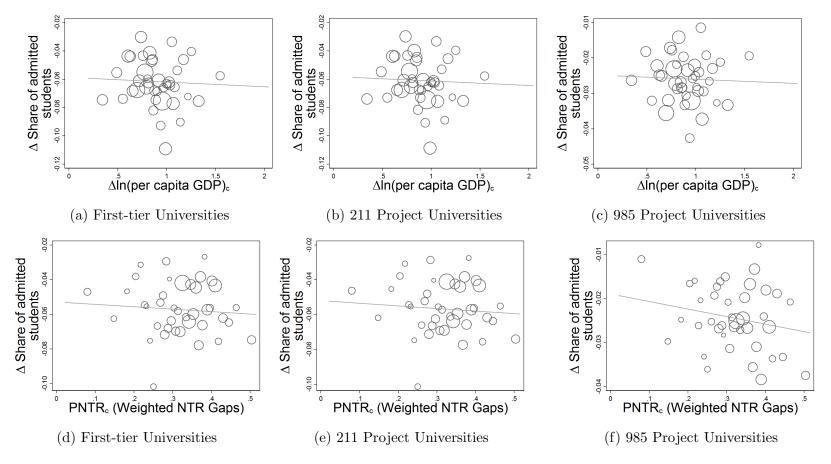

Figure E.5: The Change in Housing Prices, Rental Income, and Other Income

Notes: The figures display information about rental properties in China using micro data from 2002-2007 UHS. For each, we take the average across all households. The top figures show the average number of properties per household along with the share of households who lease properties. The bottom figure shows the average share of income from rents (which is zero for most households) and the rise in household income by year. The figures in the left column construct statistics using all households, while those in the right column are conditional on households that own property.

Figure E.6: Correlation between PNTR and Household Service Expenditure and Borrowing post WTO

Notes: Figures show binned scatter plots of the relationship between PNTR exposure and posttreatment growth in outcomes. The plots show 40 equal-size bins, weighted by population size in each bin. Data on expenditure on services and borrowing are from the Urban Households Survey, with the outcomes being the change from 2002 to 2007. Service expenditure shares are total service expenditures over household expenditures. Borrowing is measured as total borrowing expenditures over household income. For each plot, we report the coefficient and its associated p-value, given heteroskedasticity-robust standard errors, of a regression of the outcome on PNTR exposure.

Notes: The figure shows bin-scattered plots that reveal the correlation between the change in the share of admitted students by elite universities and (a) top row: per capita GDP growth rate by city, and (b) bottom row: PNTR gap. Per capita GDP and college shares are computed as the difference between 2005 and 2011. City population in 2005 is used as the weight. The aggregate number of students admitted by universities in each city is computed from the National College Entrance Examination data provided by the China Institute for Educational Finance Research at Peking University between 2005 and 2011. We aggregate the micro-level data to obtain the number of admitted students by student's city of origin, university, and year, based on which we calculate the year-city-specific share of admitted students by elite universities.

Table E.3: Effect of PNTR on the Difficulty in Entering Elite Chinese Universities

Notes: City-level regressions show the effect of PNTR gaps (top row), GDP growth (middle row) and GDP per capita growth (bottom row) on the growth in the share of admissions in top universities between 2005 and 2011. The aggregate number of students admitted by universities in each city is computed from the National College Entrance Examination data provided by the China Institute for Educational Finance Research at Peking University between 2005 and 2011. We aggregate the micro-level data to obtain the number of admitted students by student's city of origin, university, and year, based on which we calculate the year-city-specific share of admitted students by elite universities. All regressions control for region-level fixed effects, where the region is the first (of four) digit in the prefecture code.

F Intermediary Education Consulting Firms

We assess whether intermediary education consulting firms/study abroad agencies play a role in shaping the relationship between PNTR exposure and student out-migration. Such firms professionally assist students in the college application process, and may play an important role in spreading information on US education opportunities. Since it is difficult to separate their growth from the rise in international study more broadly, we instead use their pre-2002 geographic distribution to determine to what degree these intermediaries might have facilitated the process.¹⁴ For related reasons, we do not view them as part of the mechanisms above as their proliferation likely follows as a response to the interest in studying abroad, and they can be used to go to any destination. For example, we do not know if their growth captures a reduction in the cost of studying in the US specifically, as would be necessary for the information channel.

We interact the total number of these firms with PNTR exposure in Table F.1, and do find that the interaction is positive, although not significant at the 10% level. The PNTRcoefficient falls relative to the baseline specification, providing some evidence that cities with a larger number of agencies created before liberalization see larger student growth. We interpret these as likely facilitators of studying abroad, with income and wealth gains as the mechanism driving household decisions.

 $^{^{14}}$ Our data includes only newly created intermediary education consulting firms by city, so we use the total of these up until WTO entry, normalized by the number of college students in that city.

Table F.1: Mechanisms: Effect of PNTR on the Number of Intermediary Study Abroad Agencies

| | Intermediary Study Abroad Agencies |
|--|---|
| PNTR _c | 0.245^{*} (0.129) |
| # New Agencies (per 10,000 college students), Pre-2002 | -0.026 (0.021) |
| $PNTR_c \ge \#$ New Agencies (per 10,000 college students) | $\begin{array}{c} 0.101 \\ (0.084) \end{array}$ |
| Obs. | 254 |
| Controls | х |

Notes: Regressions show the effect of PNTR exposure on Chinese student enrollment growth between 2002 and 2013 per thousand city residents in 2002. All regressions include the full set of controls. In this table we add to our main specification the accumulated number of new student agencies pre-2002 by city, normalized by the total number of college students in that city (in 10,000s), along with its interaction with *PNTR*. Heteroskedasticity-robust standard errors reported (in parentheses). ***p < 0.01, **p < 0.05, *p < 0.1.

G Data Appendix

| Variable | Definition/Notes | Source |
|-------------------------------------|---|---|
| ΔS_c | Long difference (2002-2013) in Chinese students that matriculate at US Universities per 1,000 city (non-hukou) residents | Student Exchange and Visitors Information Sys- tem (SEVIS); China City Statistic Yearbooks (CSY) |
| PNTR | Industry (ISIC) gap between NTR and non-NTR tariff rates in 1999 | Pierce and Schott (2016) |
| X_{ci} | Total exports (in 10,000 RMB) by city-industry pairs | China Custom Data |
| 1990 employment | Calculated using data from China's One-Percent Population Census of 1990 | 1990 Population Census |
| Pop_c | City-level population (in 1,000s) –various used in the text, which are available annually, for urban and rural. | China CSY |
| GDP_c | GDP (in 10,000 RMB) | China CSY |
| Export licenses | Fraction of export revenues in total exports within an industry that is licensed to export directly in 2000 | Bai, Krishna and Ma (2017) |
| Contract intensity | Proportion of intermediate inputs employed by a firm that re- quire relationship-specific investments by the supplier (with the 1997 United States I-O Use Table). | Nunn (2007) |
| Import tariffs | The applied tariff rates by China in 2000, averaged across origins | World Integrated Trade Solution (WITS) |
| Input tariffs | 2002 input-output table for China, available for 120 industry groups ("scodes") of which 70 are manufacturing, combined with output tariffs during that year | WITS and Annual Survey of Industrial Produc- tion (ASIP) |
| Labor over value-added | Based on firm-level survey, aggregated to the industry level | ASIP |
| Capital over value-added | Based on firm-level survey, aggregated to the industry level | ASIP |
| Return on assets | Based on firm-level survey, aggregated to the industry level | ASIP |
| Return on equity | Based on firm-level survey, aggregated to the industry level | ASIP |
| Indicators from Table 4 | Log Change in: college and middle school enrollment; GDP; employment; FDI flows; real-estate investment. Plus, the share of manufacturing workers in employment and the Share of cap- ital in output in 1994 | China CSY |
| Demographic indicators (Table 4) | Share of 18 year olds in the population and the share of college educated workers in 1990 | 1990 Population Census |
| In- and out-migration | With data on skilled and unskilled migration, we compute log | 2000 and 2015 Population \tilde{c} |
| changes | change (2000-2015) in probability of out-/in-migration by city | Census |
| Share of households af- | Change in share of households (2002-2007) whose total house- | Urban Household Survey |
| fording tuition | hold income accumulated over 10 years meets or exceeds the cost of a 4-year US degree | (UHS) and authors calculations |
| Income sources | Real estate income includes rental income and income from the sale of property. Other income sources directly from UHS | UHS |
| House price | Self reported house valuations | UHS |
| Commercial price | Commercial house price data starts in 2002. | Wind Bank dataset |
| Industry skill shares | Industry-specific high-skill and low-skill specific skill shares are produced with employment by skill level. Industries labeled as "skill-intensive" if above the median across all industries. We then produced the $PNTR_c$ using the subset of skilled and unskilled industries separately. | ASIP (China) and Amiti and Freund (2010) (In- donesia) |
| # of new study abroad agencies | Aggregate entry of newly created "intermediary education con- sulting firms" from 1990-2001. We categorize firms as agencies with textual analysis from the registration database. | China Firm Administra- tive Registration Database |

Table G.1: Variable List with Definition, Notes and Source

G.1 Detail on Sources

USCIS International Students Data

Our primary outcome data comes from an individual-level file of F-1 visa recipients obtained from the U.S. Immigration and Customs Enforcement group of the Department of Homeland Security through a Freedom of Information (FOIA) Request, covering the period 2000 to 2013. These data are not available for previous years. These data identify each student's intended degree, subject of study, post-secondary institution in the U.S., city and country of origin, along with variables indicating cost of attendance, financial support, and the period of study.

These data are stored by the Student and Exchange Visitor Program (SEVP), which is a part of the National Security Investigations Division and acts as a bridge for government organizations that have an interest in information on nonimmigrants whose primary reason for coming to the United States is to be students. SEVP maintains the Student Exchange and Visitors Information System (SEVIS).

SEVP requires that students provide their permanent address, which helps determine their prefecture city of origin. We aggregate the individual-level data to obtain total students by year of entry and city of origin, and also group subtotals by program/funding characteristics.

China Customs Database and Tariff Data

The tariff data comes from the Trade Analysis and Information System (TRAINS) database, which is maintained by the United Nations Conference on Trade and Development (UNCTAD). The raw tariff data is withdrawn with the simple average at the level of country-HS 6-digit.

Information on city exports and imports is derived from the China Customs Database, which covers the universe of Chinese exports and imports, and was harmonized and generously provided by the University of California, Davis, Center for International Data (Feenstra et al., 2018). The data reports the annual trade information on values, quantities, and partner countries at the HS 8-digit level for all Chinese cities in the period under investigation (i.e., 1997 to 2014). As the industry classifications used in tariffs and the China Customs Database (i.e., HS 6-digit) are different from the one in the Annual Survey of Industrial Production (i.e., Chinese Standard Industrial Classification 4-digit), we correspond them to the International Standard Industrial Classification (ISIC) Revision three at the 4-digit level to construct various trade shock measures in practice.

Firm Survey Data

The annual city-industry-specific employment is sourced from the Annual Survey of Industrial Production (ASIP) conducted by the National Bureau of Statistics (NBS) of China (1998 to 2013). The dataset surveys all types of firms (state-owned / non-state-owned) whose revenue is more than five million RMB each year in the manufacturing sector. The sample size varied from 165,119 in 1998 to 336,768 in 2007. ASIP provides us with employment at the firm level, and we aggregate it to obtain total employment at the city-industry level. Notably, the ASIP industry classification uses the China Standard Industrial Classification (GB/T4754-1994 and GB/T4754-2002) at the 4-digit level. To be consistent with the tariff and trade data, we concord the China Standard Industrial Classification to the International Standard Industrial Classification Revision three at the 4-digit level using the crosswalk provided by the NBS of China.

Firm Census Data

To measure the number of newly created manufacturing plants by city and year, we use the (second) economic census of China carried out by the NBS in 2008. The data covers all firms in all sectors engaged in economic activities by the end of 2008, including all state-owned and private enterprises spanning all manufacturing and non-manufacturing industries. The data contains rich information on firm characteristics, including the year when the plant was created, in addition to basic firm information, balance sheet information (such as investments, output, value-added), and other information on economic activities. The industry classification in census data uses the China Standard Industrial Classification (GB/T4754-1994 and GB/T4754-2002) at the 4-digit level. We count the number of new firms by city and year based on a firm's year of establishment, which equals the number of firms in city c established in year t.

Information on Study Abroad Agencies

The Ministry of Education of China frequently reported the list of qualified study-abroad agencies in China. However, there are many cases where only the headquarter or main branches of the group are shown on the list.¹⁵ Instead, to obtain the number of study-abroad agencies by Chinese city and year, we apply textual analysis to names of firms in the Firm Administrative Registration Database that is maintained by China's State Administration for Industry and Commerce (SAIC).¹⁶

In Table G.2, we first summarize the keywords frequently appearing in the name of study abroad agencies based on the list reported by the official website of the Ministry of Education of China, which we use to identify whether an enterprise, in administrative registration data, is a study abroad agency.

With the keywords, we apply the textual analysis to the names of the universe Chinese firms in the administrative registration data, and count the number of firms containing these keywords by city and year. In such a way, we compute the number of newly created study-abroad agencies by city and year. In Figure G.1 we plot the average number of study-abroad agencies per city over time. The average number of study-abroad agencies per city grew from 0.03 in 1990 to 1.42 in 2002 and 36.58 in 2013.

¹⁵For instance, New Oriental Education & Technology Group has many branches across Chinese cities, but the list may only report its headquarter in Beijing or the main branch in Zhejiang. For an example of the 2007 list, see http://www.gov.cn/zfjg/content_798542.htm.

¹⁶The data reports the administrative information of the universe of enterprises in China. The data contains basic information such as firm name, firm location, industry classification, year of establishment, ownership type, legal representative, shareholders, and registered capital value.

| English Meaning | Chinese Keywords (Pinyin) |
|-----------------------------------|--|
| study abroad | liu2xue2, chu1guo2fu2wu4, chu1guo2qi3hua4 chu1guo2zi1xun2, chu1guo2ren2yuan2fu2wu4 |
| education and cultural exchange | jiao4yu4wen2hua4jiao1liu2, jiao4yu4jiao1liu2 jiao4yu4guo2ji4jiao1liu2, wai4fu2dui4wai4jiao1liu2 |
| education and cultural consulting | ren2cai2jiao1liu2, ren2cai2ji4shu4he2zuo4 jiao4yu4guo2ji4zi1xun2, jiao4yu4zi1xun2 jiao4yu4xin4xi1zi1xun2 |
| education and cultural service | jiao4yu4guo2ji4fu2wu4 |

Table G.2: List of Frequent Keywords in Firm Names of Study Abroad Agencies

Notes: Chinese pinyin for each keyword is displayed in the second column.

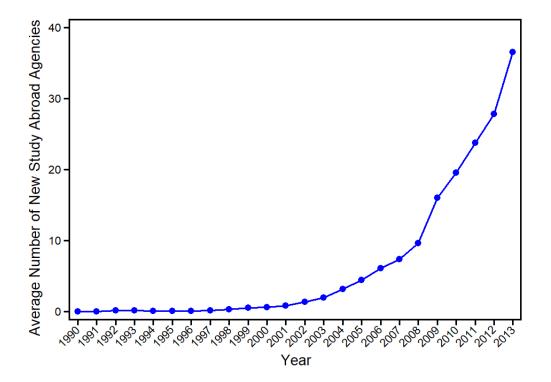

Figure G.1: Average Number of Newly Created Study Abroad Agencies

Local China College Students Admissions Data

The aggregate number of students admitted by universities in each city is computed from the National College Entrance Examination (NCEE) data provided by the China Institute for Educational Finance Research at Peking University. The data covers the universe of students enrolled in Chinese universities and colleges between 2005 and 2011. Other details on the data and the background of the NCEE are discussed in Zivin et al. (2018). We aggregate the micro-level data to obtain the number of admitted students by student's city of origin, university, and year, then we calculate the year-city-specific share of admitted students by elite universities.

We measure the eliteness of a Chinese university according to its membership in the first-tier class, 211-Project, and 985-Project.¹⁷ In terms of eliteness, 985-Project universities are typically considered better than the 211-Project universities, followed by the first-tier universities.

Background: The National College Entrance Examination

The NCEE (i.e., *Gao Kao* in Chinese) is so far the most important channel for higher education admissions in China. In practice, the same subjects are tested in every province, while the testing contents may vary. Each university assigns a predetermined admissions quota to each province before the test, and will admit applicants from the highest to the lowest scores until the provincial quota is filled. Students compete within a province based on the total score to be admitted to a university, and they do not compete across provinces. Therefore, students from different prefecture cities within a province will be faced with the same NCEE policy.

¹⁷Regular colleges and universities can be classified into three tiers according to the admissions process. The first-tier universities are generally considered as the elite or key universities, whose admissions process takes place before the second- and third-tier universities (first-tier universities also require higher cut-off scores for admission). The 211-Project refers to the proposal to "enhance the quality of 100 colleges in the 21st century." In 1998, the Chinese government launched a program to increase financial support for elite universities, and this program is referred to as the 985-Project. The universities in the 985-Project lists are typically considered better than the ones in the 211-Project lists. In 2011, there were 39 universities on the 985-Project list, and 112 on the 211-Project list.

Urban Household Survey Data

The Urban Household Survey (UHS) is conducted by the National Bureau of Statistics of China (NBS), which is similar to the Current Population Surveys in the United States and adopts a stratified and multi-stage probabilistic sampling scheme. The data is a rotating panel where the full sample is changed every three years. The UHS reports household information and economic characteristics, such as the household income of different types. The data have been widely used, and detailed information on the UHS is provided by Han, Liu and Zhang (2012) and Ding and He (2018). The UHS has been used to study wage inequality (Yang, 1999; Ge and Yang, 2014), and we follow their work in making changes in the city's average outcome between 2002 and 2007. This constitutes more than 30,000 households and more than 120,000 individuals each year. This covers between 151-204 cities for the analysis, and we are missing data in the last few years of our student sample.

China Population Census Data

To construct the PNTR exposure measure that uses city-level employment shares by industry in 1990, we use China's One-Percent Population Census data of 1990 to compute city-level employment shares by industry in 1990. As the industry classification in 1990 Population Census uses the China Standard Industrial Classification (GB/T4754-1984), we correspond them to the International Standard Industrial Classification (ISIC) Revision three at the 4-digit level to construct various trade shock measures in practice.

To trace migration flows across Chinese cities, we use China's One-Percent Population Census data of 2000 and 2015. Notably, the 2015 census is the latest data with restricted public access. The census provides detailed information on individuals' demographic and economic characteristics, such as education levels, employment status, hukou location, and current residential city. Skilled individuals refer to those with a college degree or above, and the rest would be unskilled. We construct two measures to control for internal migrations, namely: (1) the probability of out-migration; and (2) the inflow of migrants as a share of a city's total population. Both measures are based on five-year period metrics and for both skilled and unskilled individuals. Specifically, let $L_{od,10-15}^{S}$ and $L_{od,10-15}^{U}$ denote the skilled (S) and unskilled (U) migration flows from city o to city d during the period 2010-2015, respectively. The probability of out-migration for skilled and unskilled workers are computed as

$$OUT_{o,10-15}^{T} = \frac{\sum_{\forall d \neq o} L_{od,10-15}^{T}}{\sum_{d'} L_{od',10-15}^{T}}, \quad T \in \{S, U\}$$
(10)

The inflow of migrants as a share of a city's total population is computed as

$$IN_{d,10-15}^{T} = \frac{\sum_{\forall o \neq d} L_{od,10-15}^{T}}{\sum_{o'} L_{o'd,10-15}^{T}}, \quad T \in \{S, U\}$$
(11)

where migration flows $L_{od,10-15}^S$ and $L_{od,10-15}^U$ are calculated as the aggregate outcome of decisions made by individuals in the 2015 Census. Likewise, we use the 2000 Census to compute $OUT_{o,95-00}^T$ and $IN_{o,95-00}^T$ for $T \in \{S, U\}$.

China City Statistical Yearbooks

The data on city GDP, population, education, investment, foreign direct investment, government spending, government income, and other economic indicators in the analysis come from the City Statistical Yearbook of China (various issues from 1997 to 2014). The City Statistical Yearbook of China is compiled by the National Bureau of Statistics of China and has been widely used for studying social and economic development at the prefecture city level.

Wind-Economic Database

The data on average house prices (Chinese yuan per square meter) are from the Wind-Economic Database. Commercial housing prices start in 2002, and residential housing prices in 2005. We can track house prices between 196 and 204 of the 275 cities in our study. The Wind-Economic Database is one of the most comprehensive databases on China's macroeconomy. The Wind data reports over 1.3 million macroeconomic and industry time-series data points sourced from various government agencies, such as the National Bureau of Statistics and provincial and municipal Bureaus of Statistics.
